## **Does patenting increase the private incentives to innovate? A microeconomic analysis**

### **Abstract**

This paper examines whether patenting increases the private incentives to innovate in manufacturing. To study this issue, we build a model in which the value of an innovation depends both on the type of innovation implemented (product, process) and on the existence of a patent protection or not. We obtain a three-equation model that links the values of product and process innovations to the value of patent protection. This model and the feature of the data imply the estimation of a censored trivariate Probit model. We reach two main conclusions. First, the value of patent rights increases the incentives to innovate in products but not in processes and, conversely, the value of product innovations only – and not the one of process innovations – increases the incentives to patent. Second, we find that the distributions of product innovations and of patent values are skewed contrary to the values of process innovations. A significant share of the skewness in product values would come from the efficiency differences of intellectual property rights between the different activities.

## **Les brevets accroissent-ils les incitations privées à innover ? Un examen microéconométrique**

### **Résumé**

Cet article examine si les brevets accroissent les incitations privées à innover dans l'industrie manufacturière. Pour cela nous construisons un modèle où la valeur d'une innovation dépend à la fois du type d'innovation réalisée et de son éventuelle protection par un brevet. On en déduit un système à trois équations reliant les valeurs des innovations de produit et de procédé à la valeur de la protection par le brevet. Ce modèle permet de justifier l'estimation d'un modèle Probit trivarié et censuré. Nous parvenons à deux résultats principaux. Premièrement, la protection par le brevet augmente l'incitation à innover en produit mais pas en procédé et, réciproquement, seule la valeur des innovations de produit - et non celle des innovations de procédé - augmente l'incitation à breveter. Deuxièmement, les distributions des valeurs des brevets et celles des innovations de produits sont asymétriques, à la différence des innovations de procédé. Une part significative de cette asymétrie viendrait des différences d'efficacité de la protection par le brevet entre les différentes activités.

## Introduction

*« Patent regimes play an increasingly complex role in encouraging innovation, diffusing scientific and technical knowledge, and enhancing market entry and firm creation. As such they should be subject to closer scrutiny by science, technology and innovation policy makers. »*

*(OECD Ministers of Science and Technology,  
Conclusions of January 2004 meeting)*

Since information has the characteristics of a public good, it is generally agreed that the market will fail to provide a sufficient production of knowledge. The production of knowledge by private agents is affected by several imperfections that prevent an optimal R&D investment by the market. Knowledge has non-rivalry and non-exclusion properties that drive the private return on knowledge below its social return. Therefore, R&D has been a long-standing field of state intervention in advanced countries. Different types of policy measures have been implemented in order to stimulate the production of knowledge. A first type of intervention is to create public research institutions in order to encourage fundamental research, which is the source of many industrial applications. A second type of measure aims at reducing the private cost of R&D: this includes R&D subsidies to firms (David, Hall and Toole, 2000; Duguet, 2004), R&D tax credit (Hall and Van Reenen, 2000), support to cooperative R&D (Jacquemin, 1988; Jorde and Teece, 1990; Cassiman and Veugelers, 2002). A third set of measures aims to encourage research by increasing the private return on R&D. One manner to reach this objective is to set a patent system in order to weaken the non-exclusion property of knowledge, by granting property rights on immaterial goods. The choice between these systems, or their specific combination in each country, will depend on the common beliefs about the efficiency of a direct state intervention versus a law system whose use is left to market participants.<sup>1</sup> The evaluations that have been performed on

---

<sup>1</sup> The use of the R&D tax credit is also left to the discretion of market participants, but it can be changed by the state according to a policy, contrary to property rights that are more stable over time. The direct interventions allow for active innovation policies, while the patent system let the initiative of innovation decisions to the market participants.

subsidies and tax credit conclude that these measures are efficient (in the sense that they increase total R&D investments); the issue of the evaluation of the patent system has been less investigated.

Another motivation for this paper is based on empirical considerations (Figures 1 and 2): the use of patents has considerably increased over the last two decades in the most technologically advanced countries. The interpretation of this evolution is however ambiguous. It is possible that the increase of the number of patents results from an increase of the number of patentable innovations and, in this case, the reinforcement of patents rights that occurred over the same period could have had a positive effect on innovation. But another interpretation is also conceivable: this rise in the number of patents could express strategic considerations related to patent applications, like preventing litigation or the will to improve the bargaining power in technological negotiations (Duguet and Kabla, 1998). In the latter case, the reinforcement of patent rights could have been neutral on welfare, or even negative if we account for the social cost of the patent system.

**Figure 1: Number of patent applications in Europe**

Source: OCDE, Patent Database, July 2003

From a social viewpoint, the design of a patent system should result from a trade-off between the social costs and benefits. The gains of the reinforcement of intellectual property rights (IPRs) result from the rise of the number of innovations and from a greater diffusion of knowledge during the patent life; the costs of the patent system include the inefficiencies related to market power and the cost of the judicial system. In the literature, this situation has often been summarized by the trade-off between dynamic efficiency (new products, new processes) and static efficiency (competitive pricing). From the firms' point of view, patent applications are interesting when the ability of the patent system to prevent imitation is sufficiently strong to compensate the legal and "bearing" costs of the patents.

**Figure 2: Number of patents granted in the United States**

Source: OCDE, Patent Database, July 2003

The empirical studies conducted on this topic remain cautious. The results obtained so far seem however to depend strongly on the activity considered. Overall, a first set of studies conclude that the patent system would have had a positive effect on innovation in pharmaceuticals and chemicals (Grabowsky and Vernon, 1985; Park and Ginarte, 1995 at the aggregate level, Arora, Ceccagnoli and Cohen, 2003 and, in a lesser extent, Branstetter and Sakakibara, 2001). A second set of studies stresses that the differences in property

rights modify the choice of the country of application and the direction of technological change, that is the domain in which firms' R&D investments are performed. Moser (1999), from nineteenth century data, shows that the firms that operate in countries where there is no patent system tend to direct their innovations in the activities where secrecy is efficient compared to patenting. Lerner (2001) finds that, over the period 1850-2000, the countries that have reinforced their property rights have attracted more innovations from the other countries but have not made more innovations of their own. Last, a third set of studies reach conclusions that are less favorable to the patent system. Hall and Ziedonis (2004) show that the doubling of the patent to R&D ratio in the semiconductor industry would result mostly from the will to avoid litigation, a conclusion similar to that of Duguet and Kabla (1998) on French manufacturing. These strategic considerations are also omnipresent in the studies by Levin et al. (1987) and Cohen, Nelson and Walsh (2000). In service activities, Bessen and Hunt (2004) conclude that the extension of property rights to software would have led to a decrease of R&D investment at the firm level. The latter conclusion, unfavorable to the patent system, meets other considerations on the potentially harmful effects of patent rights on innovation output when knowledge is cumulative. Thus, Bessen and Maskin (2002) emphasize that an activity like software has achieved a remarkable development *without* a patent system.

This paper scrutinizes the effect of the patent system on the innovation output of the French manufacturing firms. The restriction to manufacturing corresponds to the field of patent rights in France. Compared with the previous literature, we develop the analysis in two directions. Our first contribution is to study the causality that goes from the value of patents to the value of innovations – or the contribution of patenting to the output of research investments – while the previous studies have focused on the other causality. We do it in a setting that allows for a simultaneous determination of the values of patenting and of innovations. Our second contribution is to allow for differences of appropriation behavior depending on the type of innovation considered (products, processes). Thus, we extend the previous empirical works, which suggest that the patents would be more efficient at protecting products rather than

processes; the latter being more efficiently protected by secrecy. Our model allows for testing that assumption.

We reach two main conclusions. On the one hand, patent protection increases the incentive to innovate in products but not in processes. Conversely, process innovations do not contribute to increase patenting once product innovation is accounted for. On the other hand, while the distribution of the values of processes is symmetric, the distributions of the product and patent values are skewed. A large part of product innovations have a small value and a small part a large value. This skewness would partly originate in the skewness of the efficiency of property rights among lines of business.

In the first section, we present a model that accounts for the interdependence between the value of patents and the values of product and process innovations. The second section presents the data and the estimation method is detailed in section 3. It accounts for the fact that one can observe a patent when a firm has innovated only (selection bias) and allows for testing the validity of the model (overidentification) constraints. The results are discussed in section 4.

## I - Model

The model that follows represents one way to interpret our econometric application. It gives a justification to the simultaneity relationships between the decisions to innovate and to patent, as well as to establish the identification constraints of the system that we estimate later. Other models may be compatible with our estimation.

We consider a firm facing a three-step decision process. In the first step, the firm decides whether to invest in innovation activities or not; in the second step, the innovation output is known and its importance, denoted  $\mu$ , depends on the amounts invested in research. In the third step, the firm decides whether it applies for a patent, knowing both the value of its innovation and its appropriability (a random variable denoted  $\varepsilon$ ).<sup>2</sup> We solve this problem by backward induction.

### *1.1 Decision to patent*

At the last step, the value of innovation without protection, denoted  $\mu$ , and the appropriability disturbance, denoted  $\varepsilon$ , are known. The firm compares the values of its innovation with and without a patent protection. The value of a patented innovation can be written:

$$V(\mu, \varepsilon) = (1 + P(\varepsilon, \mu, X_{\text{appro}})) \times \mu,$$

where  $P(\cdot)$  is the patent premium and  $X_{\text{appro}}$  a set of explanative variables related to the appropriability of innovations at the firm level. The patent premium can be interpreted as the percentage gain of the innovation value attributable to the patent system:

---

<sup>2</sup> This random variable reflects the variations of market power granted by the patent. It could be interpreted as "success" as far as the considered innovation need to be "novel" to be patentable (novelty requirement) For instance, the actual life of a patent may vary from one line of business to another, depending on the quantity of information disclosed in the patent document. If the information has a strong diffusion and the innovation is perfectible, the competitors can leapfrog the patented innovation and make it obsolete.

$$P = \frac{V}{\mu} - 1.$$

Extending Arora, Ceccagnoli and Cohen (2003), we assume that the patent premium can depend on the quality of the innovation. For our application, we will assume later than:

$$P(\varepsilon, \mu, X_{\text{appro}}) = \varepsilon + \alpha_{\text{brev}}\mu + X_{\text{appro}}\beta_{\text{appro}} - 1.$$

The firm will patent when the patent premium is positive:

$$P(\varepsilon, \mu, X_{\text{appro}}) > 0 \Leftrightarrow \varepsilon > 1 - \alpha_{\text{brev}}\mu - X_{\text{appro}}\beta_{\text{appro}}.$$

## ***1.2 Research investment***

At the second step, the firm has not yet observed whether its innovation is successful or not (i.e., the value of  $\varepsilon$ ) but has an idea on its distribution. We denote  $\Phi(\cdot)$  the cdf and  $\phi(\cdot)$  the pdf of this distribution (assumed to be gaussian in the application). We also assume that the quality of the innovation depends on the amount of R&D invested, denoted  $r$ , in the following manner:

$$\mu = f(r, X_{\text{inno}}),$$

where  $X_{\text{inno}}$  denotes the determinants of innovation different from research investments.

The firm chooses its amount of R&D,  $r$ , by maximizing its expected profit, denoted  $\bar{\Pi}$  :

$$\bar{\Pi} = \int_{P>0} \underbrace{(P(\varepsilon, \mu, X_{\text{appro}}) + 1)}_V \mu \phi(\varepsilon) d\varepsilon + \int_{P\leq 0} \mu \phi(\varepsilon) d\varepsilon - r$$

under the constraint  $\mu = f(r, X_{\text{inno}})$ . It is useful to define the expected patent premium, denoted  $z$ :

$$z = \alpha_{\text{brev}}\mu + X_{\text{appro}}\beta_{\text{appro}} - 1$$

so that the expected profit can be written:

$$\bar{\Pi} = \mu (1 + \phi(z) + z \Phi(z)) - r.$$

The first-order condition defines the optimal R&D investment:

$$\begin{aligned} \frac{\partial \mu}{\partial r} \times [1 + \phi(z^*) + z^* \Phi(z^*)] + \frac{\partial z}{\partial R} \times \mu^* \Phi(z^*) &= 1 \\ \Leftrightarrow \frac{\partial \mu}{\partial r} [1 + \phi(z^*) + z^* \Phi(z^*) + \alpha_{\text{brev}} \mu^* \Phi(z^*)] &= 1 \end{aligned}$$

with  $\mu^* = f(r^*, X_{\text{inno}})$  and  $z^* = \alpha_{\text{brev}} \mu^* + X_{\text{appro}} \beta_{\text{appro}} - 1$ . The previous relationship

implicitly defines the optimal amount of R&D and therefore the quality  $\mu^*$  of the innovation.

This amount depends on the environment of the firm that can be decomposed into two parts:

first, the innovative environment summarized by the variables in  $X_{\text{inno}}$  and, second, the

institutional environment summarized in the  $X_{\text{appro}}$  vector. The latter includes the

appropriation possibilities in the firm's line of business. It is important for estimation to

remark that the appropriability conditions intervene in the first-order condition through the

expected patent premium  $z^*$  only. Using the innovation function  $\mu = f(r, X_{\text{inno}})$  at the

optimum, we get the following two-equation system:

$$\begin{cases} \mu^* = \mu(z^*, X_{\text{inno}}) \\ z^* = z(\mu^*, X_{\text{appro}}) \end{cases}$$

One contribution of this study is to measure the firm-level incentives that patents provide to

innovation; this effect is measured by  $\partial \mu^* / \partial z^*$ . Notice that the quantity that is commonly

estimated in the previous literature is close to  $\partial z^* / \partial \mu^*$ . Furthermore, the previous equations

highlight the identification conditions essential for the estimation to follow. The appropriation

condition  $X_{\text{appro}}$  affects innovation output through the patent premium only, and the

innovative environment affects the patent premium through the value of innovation only.

Therefore we have at least one variable that intervenes in one equation and not in the other; needless to say that this exclusion constraints needs to be tested. The estimation method we use – namely, asymptotic least squares – allows for testing these overidentification constraints directly. On our data, these restrictions are accepted at conventional levels of significance.

### ***1.3 Econometric model***

In order to estimate the theoretical model we have to account for the following data constraints<sup>3</sup>. Firstly, the information on innovation output and on patent applications is available on the same period (1997-1999), so that we have to account for their simultaneity, at least for time aggregation reasons.<sup>4</sup> This innovation data comes from the FIT<sup>5</sup> survey. Secondly, the only information available is dichotomous; we know whether a firm has patented and whether it has innovated (in products or processes separately) so that we will need to estimate a three-equation Probit model. Thirdly, the matching of the innovation surveys with the standard R&D surveys would have made us lose a large number of firms due to differences of sampling. Therefore, we have used the CIS2<sup>6</sup> survey that provides information on the R&D expenditures over the period 1994-1996 and whose sampling is close to the FIT survey. We use the same theoretical model for products and for processes, which is possible because we focus on the patent premium; however, since we observe patenting only globally, we have to interpret the patent premium  $z^*$  as a global premium defined at the firm level and not at the innovation level. However, we show below that it is possible to decompose the patent premium between products and processes. Fourthly, we observe patenting when the firms have innovated only; therefore, we have to account for a selection bias.

---

<sup>3</sup> See below for a description of our data.

<sup>4</sup> See Mundlak (1961) for a discussion.

<sup>5</sup> FIT: Financement de l'Innovation Technologique (Funding of Technological Innovation). This survey was performed by Sessi (French Ministry of Industry) in 2000. It also provides information on the appropriation conditions.

<sup>6</sup> CIS for Community Innovation Survey. Therefore our data is comparable with the one of the other European countries. The CIS are coordinated across countries by EUROSTAT.

We account for these data limitations and use a linear version of the first order condition of our model:

$$\begin{cases} \mu_{\text{prod}}^* &= \alpha_{\text{prod}} Z^* + X_{\text{inno}} \beta_{\text{prod}} + u_{\text{prod}} \\ \mu_{\text{proc}}^* &= \alpha_{\text{proc}} Z^* + X_{\text{inno}} \beta_{\text{proc}} + u_{\text{proc}} \\ Z^* &= \alpha_{\text{brev}}^{\text{prod}} \mu_{\text{prod}}^* + \alpha_{\text{brev}}^{\text{proc}} \mu_{\text{proc}}^* + X_{\text{appro}} \beta_{\text{brev}} - 1 \end{cases}$$

where  $(\mu_{\text{prod}}^*, \mu_{\text{proc}}^*)$  are the values of product and process innovations and  $(u_{\text{prod}}, u_{\text{proc}})$

the usual disturbances of an econometric model. The third endogenous variable,  $z^*$ , is not random. Since we observe the decision to patent only, we shall rewrite the model as a function of patent premium (which is random)  $P^*$ . Since  $P^* = z^* + \varepsilon$ , we obtain the following system:

$$\begin{cases} \mu_{\text{prod}}^* &= \alpha_{\text{prod}} P^* + X_{\text{inno}} \beta_{\text{prod}} + u_{\text{prod}} - \alpha_{\text{prod}} \times \varepsilon \\ \mu_{\text{proc}}^* &= \alpha_{\text{proc}} P^* + X_{\text{inno}} \beta_{\text{proc}} + u_{\text{proc}} - \alpha_{\text{proc}} \times \varepsilon \\ P^* &= \underbrace{\alpha_{\text{brev}}^{\text{prod}} \mu_{\text{prod}}^* + \alpha_{\text{brev}}^{\text{proc}} \mu_{\text{proc}}^*}_{z^*} + X_{\text{appro}} \beta_{\text{brev}} + \varepsilon \end{cases}$$

This formulation of the model shows that we certainly face endogeneity problems since the success disturbance  $\varepsilon$  intervenes in all the equations. This property is important for choosing the estimation method<sup>7</sup>. We observe the following binary variables:

$$\text{Prod} = \begin{cases} 1 & \text{if } \mu_{\text{prod}}^* > 0, \\ 0 & \text{otherwise} \end{cases}, \quad \text{Proc} = \begin{cases} 1 & \text{if } \mu_{\text{proc}}^* > 0, \\ 0 & \text{otherwise} \end{cases},$$

$$\text{Brev} = \begin{cases} 1 & \text{if } P^* > 0 \text{ and } \max(\mu_{\text{prod}}^*, \mu_{\text{proc}}^*) > 0 \\ 0 & \text{otherwise} \end{cases}$$

---

<sup>7</sup> One has to account for cross correlations in the Reduced Form to get consistent first step estimators - see below for more precision on the estimation procedure.

$\varepsilon$ ,  $u_{\text{prod}}$  and  $u_{\text{proc}}$  are also correlated if for example some unobserved heterogeneity drives both innovative behaviour and appropriation behaviour.

The three previous binary variables are endogenous. The definition of the third variable comes from the fact that one can observe a patent application ( $P^* > 0$ ) only when the firm has innovated in product ( $\mu_{\text{prod}}^* > 0$ ) and/or in process ( $\mu_{\text{proc}}^* > 0$ ). This selection bias is important because the disturbances of the three equations are correlated. We explicitly account for it when we estimate the model.

## II - The data

### *II.1 Sample construction*

The sample results from the matching of the four following sources of firm-level data:<sup>8</sup>

1. « Financement de l'Innovation Technologique » (FIT) survey. It was collected by SESSI in 2000 in manufacturing, and provides global information over the period 1997-1999.
2. Community Innovation Survey (CIS2). It was collected by SESSI in 1997 in manufacturing and provides information over the period 1994-1996.
3. BRN administrative file. It is collected by the tax administration ("Direction Générale des impôts") and provides information about accounting data for the year 1996.
4. Line of business industry census. It was collected by SESSI in 1996 among firms of 20 employees or more and includes the decomposition of a firm's sales, employment and exports for all its lines of business.

The FIT survey covers manufacturing firms with 20 employees or more, except food industry and construction. This definition corresponds roughly to the set of innovations that are patentable in France (services cannot be patented). However, the size threshold indirectly excludes a part of the start-ups. We take the three endogenous variables of our analysis from this data set: the product innovation dummy, the process innovation dummy and the patent application dummy. We also take from this survey one of the variables needed for the identification of the model: the firms' assessment on the patent system.<sup>9</sup>

---

<sup>8</sup> The matching is performed easily since all French firms have a national identification number whose use is compulsory (called the SIREN number).

<sup>9</sup> See the appendix for a detailed presentation.

The CIS2 is the French part of the Community Innovation Survey that is coordinated by EUROSTAT. The Community surveys are performed jointly by the members of the European Union. We use the information on the innovation inputs over the period 1994-1996: internal R&D expenditures, external R&D expenditures, expenditures on equipment goods that incorporate innovations, as well as a product imitation rate at the line of business level (see appendix I).

Last, the data from BRN and EAE provide the firm-level accounting data for the year 1996: Sales, Lerner index, sales diversification index, Herfindahl index of sales concentration and an export dummy.

The four data sets have been matched from the SIREN identification of the firms. Our final sample includes 1027 firms, all engaged in (successful or unsuccessful) innovation activities.

## ***II.2 Sample statistics***

Tables 1 to 4 present some sample statistics. Overall, the firms that are involved in research activities have a median size of 191 employees. They export more than the fourth of their production. Table 2 summarizes the innovative output of these firms. The most innovative activities are electrical equipment, chemicals, electrical component, houseware and pharmaceuticals. The product and process innovations are strongly correlated, since 58% of the firms implement these both types of innovation together. Yet, a significant share of firms innovate in product only (21%). Process innovation without product innovation is less common (13%) but some industries depart from the average behavior. For instance, 45% of the firms in printing and publishing make process innovations only; the figure is 20% for wearing apparel and leather as well as metalworking. Industries in advanced lines of business can also make a strong use of processes; for instance 17% of the firms in shipbuilding, aircraft and rail make process innovations only, even though the majority of innovators in this industry make both product and process innovations (Figure 3). These differences in innovation behaviors should have consequences on the patenting behavior of

the firms: indeed, the processes are more easily protected by secrecy than the products, so that the patenting rate should be smaller in the industries that innovate strongly in processes.

**Table 1: Sample statistics**

	1st Quartile	Median	3rd Quartile	Mean

F6: Electrical components	63.0	28.8	31.5	39.7
<i>Manufacturing</i>	56.1	33.5	36.0	30.5

The lines of business where firms patent the most are ones where the codification of knowledge is the easiest and where cooperation and technological negotiations are necessary to make significant advances. It is clearly the case when knowledge is strongly cumulative. The activities where firms patent the most are (Table 3) pharmaceuticals, electrical machinery, chemicals, electrical components and non-electrical machinery (more than 60%). Some activities, on the contrary, neglect patenting. It is the case of printing and publishing (8%) where 82% of the firms innovate in processes. It is also the case in wearing apparel and leather (12%) and in textile (32%), where other protections than patent exist (trademarks, textile models). Overall, 56% of the firms patent, which is small for a sample of firms that declare they are involved in research activities.

**Table 4: Innovation and assessment of IPRs**

*The amounts are in thousand Euros*

	Sample Total	Product Innovators	Process Innovators	Both types Innovators	Patenting	Not Patenting

Table 4 presents the assessment of IPRs according to the type of innovations implemented and according to the patent practices of firms. Overall, only a third of the firms in our sample declare that IPRs are important. This figure is stable whatever the innovation profile of the firms. As expected, the firms that patent value the IPRs more than the other firms but they do

not value it importantly: 60% of the patenting firms think that intellectual property is unimportant or weakly important against 82% for the non-patenting firms.

**Table 5: Patent applications by innovating firms**

<i>ln %</i>	Product	Process	Product and Process	Product only	Process only
<b>Patenting firms</b>	93.7	76.6	70.3	23.4	6.3
<b>Non-patenting firms</b>	75.9	78.6	54.5	21.4	24.1
<b>Difference</b>	17.8	-2.0	15.8	2.0	-17.8
(standard error)	(3.18)	(3.86)	(4.45)	(3.86)	(3.18)
<b>All firms</b>	86.1	77.4	63.6	22.6	13.9

The Table 5 highlights the importance of product innovation in the decision to patent. Two interesting facts show up. Firstly, while the patenting firms innovate more often in products than the non-patenting firms, they do not innovate more in processes than the non-patenting firms. Secondly, while the patenting firms have the same probability to innovate in products *only* than the non-patenting firms, the patenting firms have a four times smaller probability to innovate in process *only* than the non-patenting firms. These two facts suggest that there is a positive association between product innovation and patenting.

The aim of our application is to study this issue more rigorously, with regression methods, in order to see by which extent the innovations are patented and whether patenting influences the innovation output.

### III - Model estimation

#### III.1 The selection bias

The structural model has the following form:

$$\begin{cases} \mu_{\text{prod}}^* &= \alpha_{\text{prod}} P^* + X_{\text{inno}} \beta_{\text{prod}} + u_{\text{prod}} - \alpha_{\text{prod}} \times \varepsilon \\ \mu_{\text{proc}}^* &= \alpha_{\text{proc}} P^* + X_{\text{inno}} \beta_{\text{proc}} + u_{\text{proc}} - \alpha_{\text{proc}} \times \varepsilon \\ P^* &= \alpha_{\text{brev}}^{\text{prod}} \mu_{\text{prod}}^* + \alpha_{\text{brev}}^{\text{proc}} \mu_{\text{proc}}^* + X_{\text{appro}} \beta_{\text{brev}} + \varepsilon \end{cases}$$

The latent variables in this model are not observable; we only observe the following dummy variables:

$$\begin{cases} \text{Prod} &= \mathbf{1}(\mu_{\text{prod}}^* > 0) \\ \text{Proc} &= \mathbf{1}(\mu_{\text{proc}}^* > 0) \\ \text{Brev} &= \mathbf{1}(P^* > 0) \times \mathbf{1}(\max(\mu_{\text{prod}}^*, \mu_{\text{proc}}^*) > 0) \end{cases}$$

A selection bias appears for the patenting dummy. It is censored by the following dummy variable:

$$\mathbf{1}(\max(\mu_{\text{prod}}^*, \mu_{\text{proc}}^*) > 0)$$

Only firms that have innovated answer to the question on patenting in the FIT and CIS2 questionnaires. If this selection was not taken into account we would have a selection bias because the disturbance of the patent equation is correlated with the disturbances of the innovation equations; our estimates will confirm it for product innovations.<sup>10</sup>

The model estimation is made in two parts:

---

<sup>10</sup> To our knowledge, the only innovation study that accounts for this kind of problem is Monjon and Waelbroeck (2003).

1. We estimate the reduced form of the model. Assuming that the vector of the disturbances is normal, we estimate this model by simulated maximum likelihood, using a GHK simulator.
2. Using the reduced form estimator, we estimate the structural form of the model by asymptotic least squares. This step is also useful for testing the overidentification constraints of the model.

### ***III.2 Simulated maximum likelihood***

The reduced form of the latent model can be written:

$$\begin{cases} \mu_{\text{prod}}^* &= X\pi_1 + \eta_1 \\ \mu_{\text{proc}}^* &= X\pi_2 + \eta_2 \\ P^* &= X\pi_3 + \eta_3 \end{cases} \quad \eta = \begin{pmatrix} \eta_1 \\ \eta_2 \\ \eta_3 \end{pmatrix} \text{ iid } N[0, \Sigma], \quad \Sigma = \begin{pmatrix} 1 & \sigma_{12} & \sigma_{13} \\ \sigma_{12} & 1 & \sigma_{23} \\ \sigma_{13} & \sigma_{23} & 1 \end{pmatrix}$$

The log-likelihood is therefore equal to:

$$\ell = \sum_{i | \max(\text{Prod}, \text{Proc})=1} \ln \Pr[\text{Prod}_i, \text{Proc}_i, \text{Brev}_i | X_i, \pi, \Sigma] + \sum_{i | \max(\text{Prod}, \text{Proc})=0} \ln \Pr[\text{Prod}_i, \text{Proc}_i | X_i, \pi, \sigma_{12}]$$

The quantities that need a specific treatment are the ones that involve triple integrals. For instance, the probability that a firm makes both types of innovation and patents, denoted  $p_{111}$ , is equal to :

$$\begin{aligned} p_{111} &= \Pr[\text{Prod}_i = 1, \text{Proc}_i = 1, \text{Brev}_i = 1 | X_i, \pi, \Sigma] \\ &= \int_{-X\pi_1}^{+\infty} \int_{-X\pi_2}^{+\infty} \int_{-X\pi_3}^{+\infty} \varphi_3(\eta_1, \eta_2, \eta_3 | X, \pi, \Sigma) d\eta_1 d\eta_2 d\eta_3 \end{aligned}$$

where  $\varphi_3(\cdot)$  is the trivariate standard normal density function. In order to evaluate the previous probability, we use Bayes' theorem:

$$\begin{aligned} p_{111} &= \Pr[\eta_1 > -X\pi_1, \eta_2 > -X\pi_2, \eta_3 > -X\pi_3] \\ &= \Pr[\eta_1 > -X\pi_1] \times \Pr[\eta_2 > -X\pi_2 | \eta_1 > -X\pi_1] \times \Pr[\eta_3 > -X\pi_3 | \eta_1 > -X\pi_1, \eta_2 > -X\pi_2] \end{aligned}$$

Since  $\Sigma$  is positive definite, there exists a lower triangular matrix  $\Lambda$  such that  $\Sigma = \Lambda\Lambda'$  (Cholesky decomposition). Therefore, we can write:

$$\begin{aligned} \eta_1 &= \lambda_{11}v_1 \\ \eta_2 &= \lambda_{21}v_1 + \lambda_{22}v_2 \\ \eta_3 &= \lambda_{31}v_1 + \lambda_{32}v_2 + \lambda_{33}v_3 \end{aligned}$$

where  $v = (v_1, v_2, v_3)'$  is a standard normal vector. We have :

$$\begin{aligned} p_{111} &= \Pr\left[v_1 > -\frac{X\pi_1}{\lambda_{11}}\right] \times \Pr\left[v_2 > -\frac{X\pi_2 + \lambda_{21}v_1}{\lambda_{22}} \mid v_1 > -\frac{X\pi_1}{\lambda_{11}}\right] \\ &\quad \times \Pr\left[v_3 > -\frac{X\pi_3 + \lambda_{31}v_1 + \lambda_{32}v_2}{\lambda_{33}} \mid v_1 > -\frac{X\pi_1}{\lambda_{11}}, v_2 > -\frac{X\pi_2 + \lambda_{21}v_1}{\lambda_{22}}\right] \end{aligned}$$

Now let  $\tilde{v}_1$  be a normal variable truncated from below by  $-X\pi_1/\lambda_{11}$  and  $\tilde{v}_2$  a normal variable truncated from below by  $-(X_2\pi_2 + \lambda_{21}v_1)/\lambda_{22}$ , we get :

$$p_{111} = \Pr\left[v_1 > -\frac{X\pi_1}{\lambda_{11}}\right] \times \Pr\left[v_2 > -\frac{X\pi_2 + \lambda_{21}\tilde{v}_1}{\lambda_{22}}\right] \times \Pr\left[v_3 > -\frac{X\pi_3 + \lambda_{31}\tilde{v}_1 + \lambda_{32}\tilde{v}_2}{\lambda_{33}}\right]$$

We make  $D = 50$  draws of  $(\tilde{v}_1, \tilde{v}_2)$  and approximate  $p_{111}$  by the following quantity:

$$\bar{p}_{111} = \frac{1}{D} \sum_{d=1}^D \Phi\left(-\frac{X\pi_1}{\lambda_{11}}\right) \Phi\left(-\frac{X\pi_2 + \lambda_{21}\tilde{v}_1^d}{\lambda_{22}}\right) \Phi\left(-\frac{X\pi_3 + \lambda_{31}\tilde{v}_1^d + \lambda_{32}\tilde{v}_2^d}{\lambda_{33}}\right)$$

where  $\Phi(\cdot)$  is the cdf of the standard normal distribution. The other probabilities are approximated with the same method; the simulated likelihood is then maximized with the routines available under SAS-IML.

The obtained estimator is convergent for  $D \rightarrow \infty$  and  $n \rightarrow \infty$  ( $n$  being the number of observations). But the GHK simulator has two particularly interesting properties. First, the

simulated quantities are continuous with respect to the parameters and this facilitates the optimization. Second, many empirical works have shown the effectiveness of this, convergence being obtained for a number of simulations much lower than for other simulation-based methods. The asymptotic conditions which ensure the convergence of the method of simulated (log-)likelihood are thus reached with a number of draws much lower than that required by other simulators.

### ***III.3 Asymptotic least squares***

The estimator of the censored trivariate Probit model obtained in the previous section is a simulated (pseudo) maximum likelihood estimator. Let  $\hat{\pi} = (\hat{\pi}_1', \hat{\pi}_2', \hat{\pi}_3')$  be the vector of the first-order parameters of the reduced form, it is consistent and asymptotically normal:

$$\sqrt{n}(\hat{\pi} - \pi) \xrightarrow{d} N\left(0, J^{-1} I J^{-1}\right) \text{ with } J = E\left(-\frac{\partial^2 \ell}{\partial \pi \partial \pi'}(\pi)\right) \text{ and } I = E\left(\frac{\partial \ell}{\partial \pi}(\pi) \frac{\partial \ell}{\partial \pi'}(\pi)\right)$$

In order to get back the parameters of the structural form of the model, we use the identification constraints of the model. For this, we introduce the exclusion matrices  $A_j$  that are defined by:<sup>11</sup>

$$X A_j = X_j \quad \text{with } j \in \{\text{prod, proc, brev}\}$$

Equating the mathematical expectations of the structural and of the reduced form of the model, we obtain:

$$\begin{aligned} X\pi_1 &= \alpha_{\text{prod}} X\pi_3 + X A_{\text{prod}} \beta_{\text{prod}} \\ X\pi_2 &= \alpha_{\text{proc}} X\pi_3 + X A_{\text{proc}} \beta_{\text{proc}} \\ X\pi_3 &= \alpha_{\text{brev}}^{\text{prod}} X\pi_1 + \alpha_{\text{brev}}^{\text{proc}} X\pi_2 + X A_{\text{brev}} \beta_{\text{brev}} \end{aligned}$$

Since the  $X$  matrix is of full column rank, we obtain the following identification constraints:

---

<sup>11</sup> These matrices are made of 0 and 1. They indicate whether a variable is present (1) or absent (0) of the equation considered.

$$\begin{aligned}
\pi_1 - \alpha_{\text{prod}}\pi_3 - A_{\text{prod}}\beta_{\text{prod}} &= 0 \\
\pi_2 - \alpha_{\text{proc}}\pi_3 - A_{\text{proc}}\beta_{\text{proc}} &= 0 \\
\pi_3 - \alpha_{\text{brev}}^{\text{prod}}\pi_1 - \alpha_{\text{brev}}^{\text{proc}}\pi_2 - A_{\text{brev}}\beta_{\text{brev}} &= 0
\end{aligned}$$

Let:

$$\beta_1 = \begin{pmatrix} \alpha_{\text{prod}} \\ \beta_{\text{prod}} \end{pmatrix}, \beta_2 = \begin{pmatrix} \alpha_{\text{proc}} \\ \beta_{\text{proc}} \end{pmatrix} \text{ and } \beta_3 = \begin{pmatrix} \alpha_{\text{brev}}^{\text{prod}} \\ \alpha_{\text{brev}}^{\text{proc}} \\ \beta_{\text{brev}} \end{pmatrix},$$

With these notations, it is possible to rewrite the identification constraints under a form that is linear according to the parameters of the structural form:

$$\underbrace{\begin{pmatrix} \pi_1 \\ \pi_2 \\ \pi_3 \end{pmatrix}}_{\pi} = \underbrace{\begin{pmatrix} \pi_3 & A_{\text{prod}} & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & \pi_3 & A_{\text{proc}} & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & \pi_1 & \pi_2 & A_{\text{brev}} \end{pmatrix}}_H \underbrace{\begin{pmatrix} \beta_1 \\ \beta_2 \\ \beta_3 \end{pmatrix}}_{\beta}$$

In the usual terminology of asymptotic least squares,  $\pi$  is called the auxiliary parameter (reduced form), and  $\beta$  is called the parameter of interest (structural form). In order to get a consistent and asymptotically normal estimator of the parameter of interest, we replace the auxiliary parameter by its estimator:

$$\hat{\pi} = \hat{H}\beta + \omega,$$

where  $\omega$  is a random variable that appears because we have replaced  $\pi$  by  $\hat{\pi}$ . The covariance matrix of this error term is equal to:

$$V(\omega) = M V(\hat{\pi}) M' \text{ with } M = \begin{pmatrix} 1 & 0 & -\alpha_{\text{prod}} \\ 0 & 1 & -\alpha_{\text{proc}} \\ -\alpha_{\text{brev}}^{\text{prod}} & -\alpha_{\text{brev}}^{\text{proc}} & 1 \end{pmatrix} \otimes I_g$$

where  $g$  is the number of explanative variables in the reduced form (i.e., the number of columns of  $X$ ). The estimation of the auxiliary equation is performed in two steps. In a first

step, we perform ordinary least squares (OLS) on the identification constraints in order to estimate  $M$  consistently. In a second step, we perform feasible generalized least squares (FGLS) using  $\hat{V}(\omega) = \hat{M} \hat{V}(\hat{\pi}) \hat{M}'$  as the covariance matrix.

Eventually, since our model is overidentifiable, we test the overidentification constraints with the following statistic:

$$S = \hat{\omega}' \hat{V}(\hat{\omega})^{-1} \hat{\omega}.$$

Under the null assumption that the overidentification constraints are valid or, more precisely, that there exists an estimator compatible with the overidentification constraints, this statistic is asymptotically distributed according to a Chi squared distribution with  $g - k$  degrees of freedom, where  $g$  is the number of (first-order) parameters of the reduced form and  $k$  is the number of (first-order) parameters of the structural form of the model. Our model appears compatible with the data (p-value : 0.865).

## IV - Results

The estimates are presented in Table 6. The reduced form of the model is useful to compare our results with the previous literature on the innovation function. The firms that have the highest probability to patent are the ones that do the more internal and external R&D, that work on several research projects at the same time, that have a large size and achieve a high mark-up rate. Most of these determinants are similar to the ones of innovation output. One can distinguish the determinants of patenting from the determinants of innovation in the structural form of the model only. However, we notice that the degree of technological opportunities does not influence patenting even though it influences both types of innovation. These results mean that, once controlled for innovation inputs, the firms that operate in the most scientifically promising activities do not patent more than the firms that operate in older activities.

The reduced form of the product innovation equation provides results that are already known in the previous literature: the probability to innovate in products increases with internal research, the degree of technological opportunities, export but also with the importance of IPRs. Two other variables have an important effect on product innovation : working on several projects at the same time increases the probability to launch new products while, at the opposite, the probability to be imitated by competitors reduces product innovation. Both effects indicate that the value of product innovation may depend on patenting. However, the structural form of the model is needed to distinguish clearly the determinants of product innovation from the determinants of patenting.

Compared to product innovations, process innovations rely on a more informal research process based on the purchase of innovative equipment goods (embedded innovations). This is in line with previous studies that obtain a similar result for the improvement of processes (Duguet, 2002). The probability to innovate in processes increases with the size of the firms, the fact to work on several projects at the same time and with the degree of technological opportunities. An important difference with product innovation is that process

innovation does not depend on the importance of IPRs. The reason often advocated to explain this result is that process innovations are better protected by secrecy. Indeed, product innovations can be purchased by the competitors and reverse-engineered, contrary to processes that are kept in house (industrial espionage is more difficult, and illegal).

The structural form is useful since it allows to study the direct interactions between patenting and innovation. Therefore it provides a way to study the issue of patent data quality, especially when they are used to measure the innovation performance in international comparisons or over time for the same country.

Our results allow concluding that only product innovations have a significant effect on patenting. Thus, the firms prefer to rely on secrecy to protect their processes. A significant part of the processes are however patented too, but it is likely that these are patented when firms innovate both in products and processes - that is when these two types of innovations are complementary. Patent statistics are therefore biased in favor of product innovations. Patenting also increase with the importance of IPRs and with the diversification of the firm. The first result suggests both that when IPRs are more efficient firms patent more and that IPRs are sometimes needed for technological negotiations. The second result suggests that when a firm operates in several lines of business it has more to lose by non-patenting than a single activity firm. Overall, the firm-level explanative variables summarize a large amount of heterogeneity between firms since most industry dummies are not significant.

The existence of patent protection originates from the will to increase the private return on research and development. We find that this mechanism works for new products only. Since patent rights increase the private returns on products it should encourage the firms to do more research than they would do without a patent protection. This point is further confirmed by another econometric result on the product imitation rate. This rate is computed at the industry level and gives the percentage of firms that launch products that are new for them but that are not new for the market. This imitation rate has a negative effect on product innovation, therefore appropriability problems remain. The original model introduces this imitation rate in all the equations of the model; the only effect that is significant at the 5%

level appears the product innovation equation. We can conclude that product imitation reduces the private return of product innovation only. In our structural model, this result also implies an indirect reduction of patenting through the reduction of the number of product innovators. Overall, the patent system encourages the private R&D investment in products. The other determinants of product innovation are in line with the previous literature: research expenditure, technological opportunities, diversification and export increase the value of product innovation.

Process innovation follows different determinants. Patent has no significant influence on the probability to innovate in processes. This point comforts the result that we have found on the patent equation: since the process is not the motivation to patent it is not surprising that patenting does not affect directly the value of process innovation.<sup>12</sup> The firms that innovate in processes prefer relying on secrecy. Furthermore, we find that the disturbance of the process and patent equations are uncorrelated. Under our normality assumption, this implies that processes and patents are conditionally independent. The variables that increase the value of processes are the expenditures on innovative equipment goods, the fact to undertake several projects at the same time and the size of the firm. These results suggest that the processes that are patented would be the ones that are strongly associated to a new product. This also implies that an important part of technical knowledge does not pass through the patent system but needs other diffusion channels, like cooperation in R&D for example.

---

<sup>12</sup> Notice that there is always an indirect influence in a structural system. Here process innovations are complementary to product innovations. Therefore, even though there is no direct connection between processes and patents, there remains an indirect relationship between product and processes. In econometric terms, our result means that there is no relationship between patents and processes *once controlled for* product innovation.

The estimations that we have performed also allow for taking a first look at the issue of the distribution of the returns on innovation. Since the contributions by Pakes and Schankerman (1986) and Scherer (1998), we know that the distributions of patent and innovation values are skewed, with some innovations highly valuable and many innovations of little value. In order to examine this issue on our data, we have computed the predictions of the latent variables of the patent, product innovation and process innovation equations. According to our theoretical model, these predictions represent a standardized estimation of the value of patenting and innovation at the firm level. The Figures 4 to 6 show the distributions of the latent variables  $(\mu_{\text{prod}}^*, \mu_{\text{proc}}^*, P^*)$ .

**Figure 4: Standardized value of product innovation****Figure 5: Standardized value of process innovation**

**Figure 6: Standardized value of patenting**

Three main results emerge from this analysis. First, the distribution of innovative processes' values is symmetric. The surface representing the projects carried out (i.e., with a positive value) is important compared to the total of "potential" projects. Second, the distribution of innovative products' values is highly skewed, as in the previous literature. Here as well, a large number of the potential innovations are carried out. Third, the distribution of patent value is clearly influenced by the distribution of product innovation value and is also skewed. However, we find a difference between the product and patent value distributions: there are much less patents carried out (i.e., positive patent premium) than product innovations; this translates the fact that many product innovations are not patented. This result is in line with the previous studies by Levin et al. (1987), Duguet and Kabla (1998), who find that patenting is not the favorite appropriation mechanism of industrial firms. Technological advances, a rapid renewal of products, or good distribution networks are other means capable of increasing the private return on research.

Finally, our estimation suggests an explanation to the asymmetry of product innovations' values. Table 6 shows that this asymmetry would come partly from the differences in the efficiency of the patent rights from one firm to another. Thus, there would be few innovations with a large value not only because there are few good innovative ideas, but also because few lines of businesses would be really protected from imitation and many lines of business are poorly protected by the available appropriation mechanisms.

## Conclusion

This study throws some light on several issues related to the efficiency of the patent system and the information content of patent data.

It clearly appears that patenting is not automatic for all among manufacturing firms and that only some types of innovations are patented. We find that product innovations are the sole significant contributors to patenting. Process innovations, at the opposite, follow ways that draw aside industrial property rights. Conversely, the patent system significantly increases the private return on product innovation but is unable to influence the private return on process innovations. These results suggest examining theoretical models in which the patent rights would not protect processes – as is often the case – but products. Our results also suggest that among the theoretical analyses performed so far, the ones that rely on product innovations should be the more relevant to patenting analysis.

Another point deals with the interpretation of patent statistics.<sup>13</sup> Our analysis shows that in France these statistics are representative of product innovations but not of process innovations. In addition, these statistics tend to overestimate the innovative output in the activities where patent rights are efficient. Therefore, the patent statistics exaggerate the innovation output of the countries that are strongly present in activities where knowledge is easy to describe in patent documents and that make new products (pharmaceuticals, chemicals, electronics, components) and to underestimate innovation output in the countries whose activities generate new processes (printing, shipbuilding, aircraft and rail, wood and paper).

---

<sup>13</sup> We do not discuss here the issue of the comparability of the patents systems of different countries.

## Appendix I : Data sources

The innovation concept used in the two innovation surveys is defined in the Oslo Manual (OECD). The technological innovations include the technologically new products and processes, as well as the important technological improvements of products and processes. Either these innovations are new for the firm and not for the market (incremental innovation), or they are new for both the firm and its market. In the latter case, we refer to it as “radical” innovation. The definition used in the survey excludes design or organizational innovations, the changes of packaging and seasonal changes.

### ***« Financement de l'Innovation Technologique » Survey (Financing of Technological Innovation Survey)***

We use the following items of the FIT survey:

1. In 1997, 1998 or 1999, has your firm launched products that were technologically innovative (or technological improved) from your firm's viewpoint? (Yes/No).
2. Do you manage several technologically innovative projects in parallel? (Yes/No).
3. Knowledge leaking: How do you assess the risk that, at the end of each step of your technologically innovative projects, other firms can benefit freely from your results? “Patent (infringement, patenting around)” (irrelevant/very weak/weak/strong/very strong).
4. In 1997, 1998 or 1999, has your firm (or the group it belongs to) applied for at least one patent in France or in another country? (Yes/No).
5. Do you consider that your main line of business is technologically: not innovative/weakly innovative/moderately innovative/strongly innovative?

***Second Community Innovation Survey (CIS2)***

We use the answers from the following questions from CIS2:

- 1 Between 1994 and 1996, has your firm launched products that were technologically innovative (or improved) from your firm's viewpoint? (Yes/No).
- 2 Between 1994 and 1996, has your firm launched products that were technologically innovative (or improved) not only from your firm's viewpoint, but also for its market? (Yes/No).
- 3 In 1996, has your firm been involved in the following innovative activities? If yes, indicate the corresponding expenditures :
  - Internal R&D;
  - External R&D (including from another firm in your group);
  - Purchase of machinery and equipments in relation to product and process innovations.
- 4 Between 1994 and 1996, has your firm applied for a least one patent in France or in another country? (Yes/No)

***Explanative variables***

1. *Lagged product innovation, process innovation and patent application dummy variables.* Available in CIS2.
2. *Importance of intellectual property rights.* This variable corresponds to the fourth question of the FIT survey. The reference value is « irrelevant »; the

intermediate value regroups « very weak » and « weak »; the highest value regroups « strong » and « very strong ».

3. *Firm-level assessment of the technological opportunities in the line of business.* Corresponds to question 6 in the FIT survey. The reference value is « not innovative »; the intermediate value regroups « weakly innovative » and « moderately innovative », the strongest value is « strongly innovative ».
4. *Innovation input variables (internal R&D, external R&D, innovative equipment and machinery expenditures).* These variables are constructed from the third question of CIS2. For each variable the reference value is the absence of any investment; the intermediate value is reached when the ratio of the investment to sales is lower than the sample median (among strictly positive values); the highest value is reached when the ratio of the investment to sales is higher than the median (among strictly positive values).
5. *Size variable.* The logarithm of sales in 1996.
6. *Diversification :* the logarithm of the Herfindahl equivalent number of lines of business (equal to the inverse of the Herfindahl index). This index is computed from the decomposition of each firm's sales among its lines of business. For a firm  $i$  that operates in  $k_i$  lines of business, we get :

$$H_i = \sum_{k=1}^{k_i} \left( \frac{S_{i,k}}{S_i} \right)^2 \quad \text{and we use } \ln(\text{DIV}_i) = \ln(1/H_i).$$

Notice that when all the shares are equal  $S_{i,k}/S_i = 1/k_i, \forall k = 1, \dots, k_i$ , the equivalent number of activities  $\text{DIV}_i$  is equal to the real number of activities  $k_i$ . When a firm is not diversified, the equivalent number is equal to one.

7. *Average concentration index.* It generalizes the Herfindahl index to multi-products firms.

Let  $H_k$  be the concentration index of the line of business  $k$  :

$$H_k = \sum_{i=1}^{n_k} \left( \frac{S_{i,k}}{S_k} \right)^2$$

where  $n_k$  that operates on market  $k$ . The average concentration index is defined by the following formula:

$$H_i = \sum_{k=1}^{k_i} \frac{S_{i,k}}{S_i} \times H_k ,$$

therefore  $1/H_i$  measures the equivalent number of firms on the average market where firm  $i$  operates. We include the logarithm of this competition measure in our regressions.

8. *Lerner index*. It is a firm level measure of market power:

$L_i = \text{EBE}/\text{Sales}$  , where “EBE” (excédent brut d’exploitation) equals valued added minus labor cost. This is an accounting approximation of  $(p - c)q/pq = (p - c)/p$ . This variable reflects the capacity of the firm to price above its (marginal=average here...) cost  $c$ .

9. *Exportation dummy* (equals one when a firm exports).

10. *Sectoral variables*. We include a full set of industry dummies at the two-digit level (NAF36) and a variable that aims to measure the probability to be imitated by competitors when one launches a new product (at the three-digit level in order to ensure identification). This variable is computed from CIS2 and should reveal the degree of competition between the innovative firms since it influences the degree of substitution between their innovative products. This variable is computed the following way and is a special case of Crépon, Duguet and Kabla (1996). Let :

- $p_k$  the percentage of product innovators in industry  $k$  (three-digit decomposition);

- $p_k^I$  the percentage of product imitators in industry  $k$ . They are defined as the firms that launched innovative products that were new for the firm but not for the market;
- $p_k^M$  the percentage of real product innovators in industry  $k$ . They launched a product that is new both for them and for the market.

We have the identity :  $p_k = p_k^I + p_k^M$  and the imitation rate equals :

$$TI_k = \frac{p_k^I + p_k^M / 2}{p_k} .$$

The coefficient 1/2 comes from the fact that, in our data, the real product innovators are always almost product imitators too.<sup>14</sup> We also computed an imitation rate from the sales of innovative products. The latter measure always gave us less good results on the regression, possibly because of measurement error.

---

<sup>14</sup> This is the difference between Crépon et al. (1996) that worked on a larger data set. See this reference for a generalization of the previous formula.

## Appendix 2: Variables on the efficiency of property rights

The variable about the assessment of the efficiency of industrial property rights relies on the answers to the following question in the FIT survey:

*“ How important do you consider the risk that, at the end of each stage of your research project, other firms can benefit freely from your results?*

*Patent (infringement, patenting around): irrelevant, very weak, weak, strong, very strong “.*

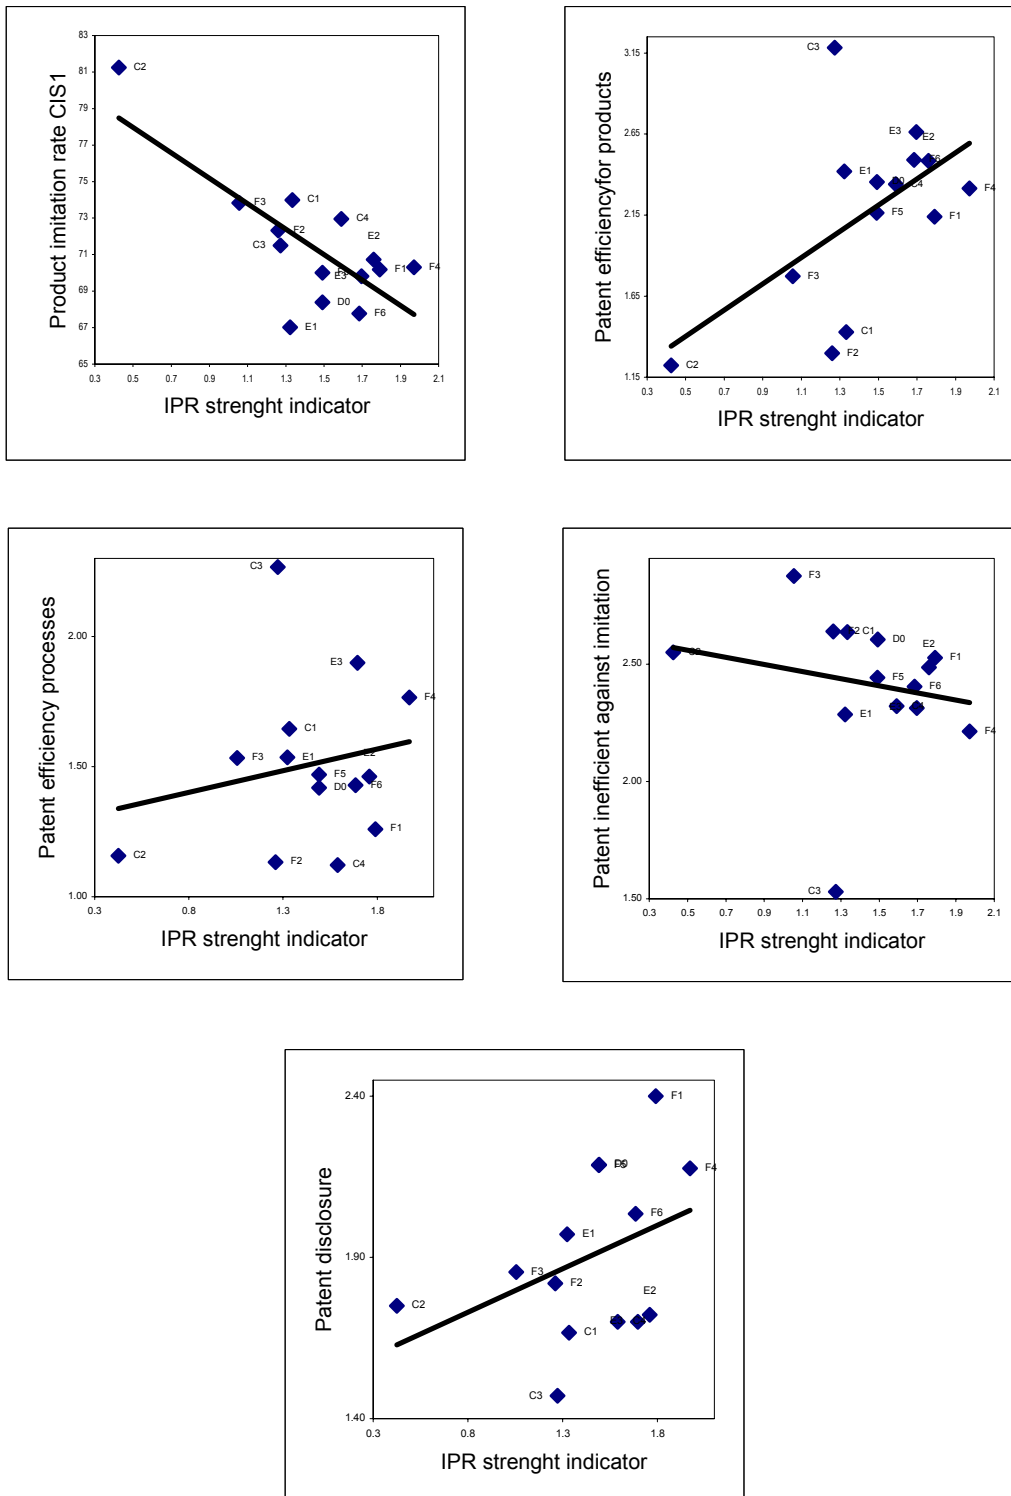

We interpret this variable as expressing the degree of importance that the firms attribute to patent protection, as well as an appreciation on the efficiency of the patent system. However, since the question is not formulated exactly in this manner, our interpretation must be validated by other measures. Therefore, we have examined the correlation between the answers to the previous question and the following measures: the judgment on the efficiency of patents available in the Appropriation survey (“Yale 2”) and the product imitation rate computed from CIS2 (1994-96). We find the following correlations between the average scores at the two digit level:

Variables	Correlation coefficient
1993 : Efficiency of patents to protect products (score 1-4)	0.59 (0.025)**
1993 : Efficiency of patents to protect processes (score 1-4)	0.18 (0.536)
1993 : Patents do not prevent imitation by competitors (score 1-4)	-0.32 (0.272)
1993 : Patents disclose too much information (score 1-4)	0.49 (0.079)*
FIT : Knowledge leaking from exploratory research	0.90 (<0.001)**
FIT : Knowledge leaking from R&D	0.96 (<0.001)**

*p-values in brackets. \*\*: significant at 5%; \*: significant at 10%.*

The Figure A.1 illustrates the previous correlations. The variable we use describing patent rights efficiency is positively correlated with the efficiency of patents variable available in the Appropriation survey (“Yale 2”) and negatively correlated with the product imitation rate computed from CIS2. It is also positively correlated with the score on the fact that patent disclose too much information.

Figure A.1 Correlation between patent efficiency related indicators

### **Appendix 3: Estimation controlling for lagged innovation and patent dummies**

This appendix presents the results we obtain when introducing the lagged dependent variables into the three regressions. The endogenous variables refer to 1997-1999 and the lags to 1994-1996. One objective of this additional regression is to capture potentially missing variables that could bias the estimates.

The results show that the lagged dependent variables capture a large part of the individual variations. Overall, the coefficients of the exogenous variables are weakened by this introduction. However the only deception is on the patent equation, since the introduction of the lagged patenting variables cancels the effects of innovation. This could come from the data limitation that we observe only the fact that a firm patents and not the number of patents (not available yet at INSEE after 1994). However, a more positive result appears in the innovation equations. While lagged product innovation is highly significant, patenting has still a significant and positive effect on product innovation. Last, patenting has still no effect on process innovation. These two last results are therefore robust to an important change of specification.
